COVID-19 Australia: Epidemiology Report 22

Fortnightly reporting period ending 2 August 2020

COVID-19 National Incident Room Surveillance Team

Unless indicated, the source of all data, including notified cases of COVID-19 and associated deaths, is the National Notifiable Diseases Surveillance System (NNDSS) to 2 August 2020. Due to the dynamic nature of NNDSS data, data in this report are subject to retrospective revision and may vary from data reported in published NNDSS reports and reports of notification data by states and territories. Case numbers for the most recent dates of illness onset may be subject to revision, due to reporting delays.

Summary

Over the past fortnightly reporting period (20 July to 2 August):

- The number of new cases reported nationally increased from 3,462 in the previous fortnight to 6,121.
- The large increase in numbers is due to multiple epidemiologically-linked outbreaks across a range of settings and locations in Victoria (97%; 5,914 cases) with very few (207) cases reported by other jurisdictions in this reporting period.
- Of the 5,914 cases reported in Victoria, all were locally acquired. Of the remaining 207 cases nationally reported, only 23% were reported as locally acquired.
- ACT is the only jurisdiction reporting 0 cases, with its last case reported on 9 July.
- A total of 71 deaths were reported, all from Victoria.
- On average, 437 cases were reported each day over the reporting period, an increase from 247 cases per day over the previous fortnight.
- Testing rates remain high across all jurisdictions, with an overall positivity rate for the reporting period of 0.7%. Victoria reported a positivity rate of 1.7% for this reporting period. In all other jurisdictions the positivity rate was 0.07% or lower.
- Overall, syndromic surveillance of respiratory illness trends continues to show very low levels compared to previous years.
- 12% of cases have required hospitalisation or intensive care.

Keywords: SARS-CoV-2; novel coronavirus; 2019-nCoV; coronavirus disease 2019; COVID-19; acute respiratory disease; epidemiology; Australia

1 This report addresses indicators listed in the CDNA National Surveillance Plan 2020.
In focus: New South Wales

In New South Wales, there have been a total of 3,831 cases reported to date, with 171 cases notified in this reporting period. Most cases occurred in March, with case numbers decreasing throughout April and May. Locally-acquired cases started to increase slightly towards the end of June and this trend has continued to date (Figure 2). Of the locally-acquired cases recently diagnosed in NSW, the majority have been linked to known cases or outbreaks with a small number unable to be linked.

NSW has maintained a high rate of testing, with over 300,000 tests conducted over the reporting period, representing a testing rate of 39.5 tests per 1,000 population. Additionally, over this reporting period, NSW cases were reported more frequently in males (rate ratio 1.1:1). This trend has remained consistent over the epidemic to date (Table 1).

Cumulatively, cases in NSW were reported most frequently in people aged 20–29 years old (793 cases) (Table 1). Of the 3,831 cases reported in NSW to date, 38 cases (1%) were in those identifying as Aboriginal and Torres Strait Islander peoples.

Overall, for NSW there have been 52 deaths attributed to COVID-19, 26 males and 26 females, all over the age of 50, resulting in a crude case fatality rate of 1.36% (Table 1).

Most cases reported in NSW have been overseas acquired, although the proportion of locally-acquired cases increased markedly in July. This shows a shift in source of acquisition from overseas to locally acquired (Figure 3). Importantly, the proportion of locally-acquired cases where a contact was not identified has remained low throughout the epidemic.

The age distribution of COVID-19 cases in NSW has changed over the course of the epidemic, with cases decreasing over time in those over 50 years of age and increasing over time in those less than 20 years of age (Figure 4). Prior to the start of June, the proportion of cases reported in school aged children (aged 5 to 17 years) was 2%. Since June this proportion has increased to 12%, while the proportion of cases reported in older adults (aged 65 and over) has decreased from 20% to 5% for all NSW cases. The median age of cases reported early in the epidemic was 45 years (interquartile range, IQR: 29 to 62), while in the later phase, the median age has reduced to 34 years (IQR: 23 to 48).

Figure 3: New South Wales COVID-19 notifications by source of infection, February–July 2020
Australian cases: descriptive epidemiology

Transmission trends

Up to 2 August 2020 there were 22,358 COVID-19 cases, including 361 deaths, reported nationally. Over the last fortnight reporting period, there were 6,121 cases, including 71 deaths. The majority of the recently reported cases were from Victoria (97%), followed by New South Wales (2.5%). A small number of cases was also reported in Queensland, South Australia, Tasmania, Western Australia and the Northern Territory (0.5%). On average, 437 cases were reported each day over the reporting period, an increase from 247 cases per day over the previous reporting period.

Since the first case of COVID-19 was identified in Australia, all states and territories have experienced COVID-19 cases, with some jurisdictions experiencing higher numbers and more community-associated transmission. These differences arise from factors including state demographics, population size, patterns of overseas arrivals in the beginning of the pandemic, and ongoing repatriation flights which have been concentrated in Melbourne and Sydney. Cases in Victoria are currently driven by community transmission, with numerous outbreaks occurring across a range of settings and locations in Greater Melbourne.

Respiratory illness trends

The internet-based syndromic surveillance system, FluTracking,\(^1\) monitors trends of influenza-like illness (fever and cough) and acute respiratory illness (runny nose and sore throat) in the community via self-reporting of respiratory symptoms from registered participants. Whilst this system is not specific to COVID-19, it monitors reports of respiratory symptoms and provides an indication of broader respiratory illness transmission.

Based on self-reports of fever and cough in the community, respiratory illness symptoms are currently low nationally, approximately five- to seven-fold lower than the historical average for this time of year. There was no evidence of increased community acute respiratory illness in Victoria despite the increase in COVID-19 case numbers (Figure 5).

Source of acquisition

As at 2 August 2020, Australia has recorded 18,367 cases of COVID-19 and 240 deaths: 49% of cases are reported as locally acquired; 40% are reported as overseas acquired; and 11% remain under investigation. Of all locally-acquired cases in this reporting period, the source of acquisition for 22% of cases was unable to be linked to a known case or cluster. This included 11 cases where a contact could not be identified but interstate travel had occurred.
Figure 5: Weekly trends in respiratory illness amongst FluTracking survey participants (age standardised), 2020 and average of the previous five years.

</table>

In this reporting period, 97% of cases have been reported from Victoria (5,914). Of these cases, 43% are reported as locally acquired with known source, 12% as locally acquired with unknown source and, due to the scale of the outbreak, 45% are under investigation, though they are likely locally acquired (Table 2, Figure 6).

For all other cases (207) in this reporting period: 82% of these cases were reported from NSW; 61% of cases are reported as locally acquired with known source; 11% of cases are reported as locally acquired with unknown source; 23% of cases are reported as overseas acquired; and 5% of cases reported are under investigation (Table 2). Overseas-acquired cases in this fortnight were reported from NSW (28), WA (14) and Qld (5) and were detected in travellers in hotel quarantine from repatriation flights.

Clusters and outbreaks

Residents of aged care facilities are at increased risk of COVID-19 infection due to the environment of communal living facilities and are more vulnerable to serious complications if they do become infected. As of 2 August 2020, there have been 1,436 cases of COVID-19 associated with 148 residential aged care facilities, with 127 recoveries and 136 deaths. Eight hundred of these cases occurred in aged care residents, with the remaining 636 cases occurring in care staff. The Commonwealth is actively supporting services with reported incidents and outbreaks of COVID-19 providing access to personal protective equipment and additional staffing resources where required. Advice and guidelines have been provided to aged care services, including the release of an outbreak management guide.

Testing

During this reporting period 889,678 tests were conducted nationally, with an overall positivity rate of 0.68%. All states except Victoria reported a period positivity of 0.07% or lower. Victoria reported a positivity rate of 1.67% for this period, which is an increase from the previous reporting period (0.84%).

A total of 4,366,141 tests have been conducted in Australia. High rates of testing have continued across the country, with the cumulative proportion of positive tests remaining low at less than 0.5% in most jurisdictions (Table 4). The low positivity rate indicates widespread testing in the community and supports the observation of low levels of disease in these areas. For the fortnight 18 to 31 July 2020, polymerase chain reaction (PCR) testing rates were highest in those aged 20 to 49 years (Figure 7).

aData in this table are based on reports of notification by states and territories.
Based on FluTracking data, currently 55% of those in the community with ‘fever and cough’ and 28% of those with ‘runny nose and sore throat’ reported being tested for COVID-19 during the most recent reporting fortnight. Testing and presentations to health services continue to show a gradual increase over time. In those experiencing influenza-like illness over the last fortnight, the most frequent respiratory viruses detected were rhinoviruses. It is recommended that anyone experiencing cold- or flu-like symptoms, such as a cough, fever, sore throat, shortness of breath or runny nose, even if these are mild, get tested for COVID-19 as soon as possible.

**Demographics of cases**

Historically, cases of COVID-19 have been reported across all age groups; however, recent reporting periods have highlighted a shift to younger populations in the cumulative totals (see Appendix B, Table B.1). Cumulatively, cases show a median age of 38 years (IQR: 25 to 57). Prior to the peak of cases in April, the population diagnosed was slightly older, with a median age of 47 years (IQR: 29 to 62) reflecting the primary source of acquisition being cruise ships. In this reporting period, the median age is 35 years (IQR: 24 to 54).

Cumulatively, people aged 90 and over have the highest rate of COVID-19 infection (158.4 cases per 100,000 population), followed by the 20–29 years age group (115.1 cases per 100,000 population) and then 30–39 years (87.0 cases per 100,000 population) (Table B.1). Children aged 0–9 years continue to have the lowest rate (24.0 cases per 100,000 population), with testing rates comparable to other age groups (Figure 8).

\(^a\) Source: NNDSS (Total cases = 18,353).  
\(^b\) Source: FluCAN, includes 21 sentinel hospitals (Total cases = 241).  
\(^c\) Source: SPRINT-SARI, includes 77 sentinel ICUs and high dependency units (HDU) (n = 318).
Across most age groups, males show a higher rate of infection than females, with the exception being in the 20–29 years age group and those aged 80 and over. The largest difference in rates between genders is observed in the 90 and over age group where females are diagnosed with COVID-19 almost 16% more per 100,000 population than are males.

In this reporting period, school-aged children account for 9.6% of all cases, which is a higher proportion than they comprise in cumulative cases (7.3%). This fortnight, 25% of cases were reported among people aged 20 to 29 years. The proportion of cases in this age group has been increasing in recent weeks, predominantly in Victoria.

Severity

International estimates of hospitalisation rate for COVID-19 vary from 10% in Canada to 29% in Europe.\textsuperscript{4,5} Currently, we lack reliable data to support this estimation in Australia. Of the 241 hospitalised cases captured in the sentinel surveillance system, Influenza Complications Alert Network (FluCAN), since 16 March 2020, twenty percent (49) were admitted to an intensive care unit (ICU); this is a similar proportion to ICU admission estimates in Canada (20%) and the United Kingdom (17%).\textsuperscript{4,6}

The case fatality rate (CFR) was highest for those COVID-19 patients aged over 80 years and admitted to ICU (CFR > 50%) (Table 5). Comparison of CFRs across levels of hospitalisation should be interpreted with caution as the sample sizes and data sources vary. Of cases hospitalised in sentinel sites, the CFR was 4.2%, which is dramatically lower than the aggregated value of 24% observed in European cases (data from 22 countries)\textsuperscript{5} and Canadian cases (33%).\textsuperscript{7} In cases with an ICU outcome (n = 247), 14% died (n = 35); this is also substantially lower than the ICU CFR reported in the United Kingdom at 52% (871/1,689).\textsuperscript{8} Given the large number of cases reported in the latter country, this may be influenced by the treatment options.

Hospital length of stay

In general, the length of hospital stay for patients with confirmed COVID-19 increased with advancing age category (Table 6). Of all age groups, those aged 60–79 years stayed the longest in hospital; this was the case for both general ward and ICU admissions. Overall, the median hospital length of stay in Australia was 6 days (IQR: 2–11 days) and the mean length of stay was 8.1 days (standard deviation, SD: 8.6 days). This is slightly lower than that reported in European Countries where median length of stay was 9 days and mean 13 days (data from approximately 5,100 cases),\textsuperscript{5} although differences in case numbers make comparison difficult. The European data also showed that length of stay increased with age, with people aged over 60 years staying for a median time of 10–11 days (mean: 13–15 days).\textsuperscript{5}

The ICU length of stay for COVID-19 patients in Australian data for survivors had a median age of 7 days (IQR: 3–17 days); non-survivors stayed for a median of 8 days (IQR: 4–13 days). This is longer than reported in the United Kingdom, for which the median values were 4 days (IQR: 2–8 days) in survivors and 6 days (IQR: 3–9 days) in non-survivors.\textsuperscript{9}

Characteristics of those with severe infection

Higher disease severity, as indicated by hospitalisation, admission to ICU, and death, has been associated with increased age and comorbidities.\textsuperscript{5} The median age for cases who have been hospitalised in sentinel sites (57 years; IQR: 38.3–71.2), admitted to ICU (62 years; IQR: 51.0–70.5) and died (82.0 years; IQR: 76.0–89.0) are higher than for cases overall (38.0 years; IQR 25.0–57.0). The ratio of males to females is similar among hospitalised cases (1.1:1); however, more males than females have been admitted to ICUs (1.8:1). The sex ratio also increases as age-group increases amongst both general hospitalised and those admitted to ICU (Figure 9). The highest number of deaths have occurred in those aged > 80 years for both males and females.

Comorbidities

Comorbidities were common in those COVID-19 cases admitted to Australian sentinel hospitals (general ward or ICU), with 78% recording at least one of the specified comorbidities; only 9% recorded no comorbidity. The proportion of hospitalised cases with no known comorbidity recorded in U.S hospital surveillance system COVID-NET was also reportedly 9%.10 By contrast, in the UK, 22.5% of 20,133 hospitalised COVID-19 cases had no recorded comorbidities.6,9 This UK study reports similar prevalence estimates for key comorbidities amongst hospitalised COVID-19 patients as found in Australian data. In sentinel Australian sites, chronic cardiac disease occurred in 29% of hospitalised cases (30.9% in the UK), diabetes in 32% (20.7% UK) and chronic respiratory disease (including asthma) in 31% of hospitalised cases (32% UK study).

Compared to ward-admitted patients, we observed higher prevalence rates amongst those admitted to ICU for almost all specified comorbidities (Table 7). A history of smoking (current or past smoker) was identified in 31% of those hospitalised (52/166) and 14% those admitted to ICU (41/292).

Symptom profile

The symptoms reported by COVID-19 cases in Australia are consistent with a mild respiratory infection in the majority of cases. The principal symptoms reported in cases (Figure B.1) were cough (42%), fever (30%), sore throat (27%) and headache (20%). Other symptoms reported include malaise, lethargy or fatigue (20%) and loss of taste or smell (10%). These are currently not standard fields in NNDSS, and are likely to under-represent those presenting with these symptoms. A small number of cases reported more severe symptoms, with pneumonia and/or acute respiratory disease (ARD) reported in 2% of cases and in 15% of deaths.

In more severe cases cough, fever and shortness of breath were the most common symptoms reported, as well as an increasing proportion reporting malaise/lethargy/fatigue or acute respiratory syndrome/pneumonia with increasing severity. The proportion reporting a loss or taste or smell dropped with increasing severity. The completeness of the symptom field in the NNDSS was 99%, with 73% of records indicating known symptoms.

<sup>a</sup> Source: FluCAN; excludes those with missing data on comorbidities or where comorbidity is unknown.
<sup>b</sup> Source: SPRINT-SARI; excludes those with missing data on comorbidities or where comorbidity is unknown.
<sup>c</sup> Includes asthma.
<sup>d</sup> Includes chronic respiratory conditions, cardiac disease (excluding hypertension), immunosuppressive condition/therapy, diabetes, obesity, liver disease, renal disease and neurological disorder.

The symptom profile of Australian cases is broadly similar to the symptoms reported by COVID-19 cases internationally. Among EU/EEA countries and the UK, a dry or productive cough and fever/chills were the most commonly reported symptoms.<sup>5</sup> Differences in reported symptoms will be influenced by differences in surveillance strategies and symptom reporting across countries.

**Aboriginal and Torres Strait Islander persons**

There have been 107 cases of COVID-19 notified in Aboriginal and Torres Strait Islander persons. This represents approximately 0.6% of all confirmed cases. Table 8 compares the remoteness of cases in Aboriginal and Torres Strait Islander persons with those in the non-Indigenous population. Approximately 28% (30) of all cases notified in Aboriginal and Torres Strait Islander persons are reported as being acquired overseas with almost half of these (13 cases) associated with cruise ships.

By gender, there is a higher proportion of cases in Aboriginal and Torres Strait Islander females (56%, 60 cases) than in non-Indigenous females (49%, 9,026 cases). The differences observed in gender for Aboriginal and Torres Strait Islander people likely reflect the small number of cases rather than any specific transmission pattern.
Table 8: COVID-19 notifications by Aboriginal and Torres Strait Islander status by jurisdiction, source of acquisition and remoteness classification as at 2 August 2020

a Excludes 1 probable Aboriginal and Torres Strait Islander case.
b Excludes 28 cases classified as overseas residents who were diagnosed in Australia.

The median age of COVID-19 cases in Aboriginal and Torres Strait Islander persons is 34 years (IQR: 22.5–52.0), which is younger than for non-Indigenous cases where the median age is 38 years (IQR: 25.0–57.0). Overall, Aboriginal and Torres Strait Islander males are reporting a slightly higher proportion of cases in the 20–29 year age group (28%) compared to non-Indigenous cases (22%) and Aboriginal and Torres Strait Islander females are reporting a higher proportion of cases in the 10–19 year and 50–59 year age groups (13% and 18% respectively) than is seen among non-Indigenous cases (7% and 13% respectively) (Figure 10).

For NNDSS, completeness of reporting in the Aboriginal and Torres Strait Islander field remains steady at 88%.

Public health response measures

Since COVID-19 first emerged internationally, Australia has implemented public health measures informed by the disease’s epidemiology (Figure 11). Key aspects of Australia’s evolving public health response are summarised in previous reports. On Friday 8 May, the Australian Government announced a three-step framework for easing COVID-19 restrictions, with states and territories easing restrictions at their own pace depending on the current public health situation and local epidemiology.

During the current reporting period, due to the evolving epidemiological and public health situation, several states and territories have re-implemented previously eased restrictions and/or implemented new restrictions (see Table 9). In Victoria, residents in metropolitan Melbourne have been placed under stage 4 restrictions, and residents in regional Victoria have been placed under stage 3 restrictions. Residents in Victoria are required to wear facemasks when leaving their home, and residents in New South Wales are strongly encouraged to wear facemasks in indoor settings with a high risk of transmission. Queensland, South Australia and Tasmania have adjusted domestic border restrictions. New South Wales and South Australia have also adjusted some restrictions on public gatherings.
Figure 10: National COVID-19 notifications by age group and sex, Aboriginal and Torres Strait Islander persons and non-Indigenous Australians

'a' Non-Indigenous' includes one person identified as gender X, and 88 non-Indigenous Australians with unknown gender.
Figure 11: COVID-19 notifications in Australia by date of illness onset to 2 August 2020 with timing of key public health measures

- **20 March 2020**
  - Travel ban on foreign nationals entering Australia.
  - Restriction of travel to remote communities.

- **18 March 2020**
  - Restrictions on indoor gatherings.

- **16 March 2020**
  - Non-essential static gatherings of >500 people banned.

- **15 March 2020**
  - All overseas arrivals required to self-quarantine for 14 days and cruise ship arrivals banned.

- **21 March 2020**
  - Select states and territories close borders to non-essential travel.

- **28 March 2020**
  - All people entering Australia required to undertake a mandatory 14-day quarantine at designated facilities (e.g., hotels) in their port of arrival.

- **29 March 2020**
  - Public gatherings limited to two people.

- **27 April 2020**
  - Start of easing restrictions in select states and territories.

- **2 August 2020**
  - Stage 4 restrictions for metropolitan Melbourne
  - Stage 3 restrictions for regional Victoria

- **8 July 2020**
  - NSW/VIC border closes
  - Stage 3 lockdown of Melbourne and Mitchell Shire

- **1 July 2020**
  - Victoria implements lockdowns on ‘hotspot’ suburbs

- **29 May 2020**
  - Victoria announces three-step plan to ease COVID-19 restrictions. Implementation to vary in states and territories.

- **19 May 2020**
  - NSW/VIC border closes

- **12 May 2020**
  - Stage 3 lockdown of Melbourne and Mitchell Shire

- **8 May 2020**
  - Government announces three-step plan to ease COVID-19 restrictions.

- **18 April 2020**
  - Stage 4 restrictions for metropolitan Melbourne

- **29 April 2020**
  - Stage 3 restrictions for regional Victoria

- **10 April 2020**
  - Stage 4 restrictions for metropolitan Melbourne

- **30 March 2020**
  - All people entering Australia required to undertake a mandatory 14-day quarantine at designated facilities (e.g., hotels) in their port of arrival.

- **5 March 2020**
  - All overseas arrivals required to undertake a mandatory 14-day quarantine at designated facilities (e.g., hotels) in their port of arrival.

</table>
International situation

On 2 August 2020, more than 216 countries, regions and areas had reported 17,660,523 COVID-19 cases and 680,894 deaths to WHO. All data reported below are drawn from the WHO Dashboard extracted on 5 August unless otherwise specified. The Americas and Europe continue to be the epicentres of the pandemic with the former representing approximately 54% of cumulative cases and 53% of cumulative deaths, and the latter representing 19% of cases and 32% of deaths. The global case fatality rate (CFR) is approximately 3.9% and is decreasing as case identification improves. The global cumulative per capita rates are 226.5 cases and 8.8 deaths per 100,000 population.

- By country, the largest numbers of cases are from: the United States of America (4,456,389); Brazil (2,610,102); and India (1,695,988).

- By country, the largest numbers of deaths are from: the United States of America (151,265); Brazil (91,263); and the United Kingdom (46,119).

In the previous fortnight the largest number of cases were reported by the Americas (57%) and the South East Asian (21%) regions, led predominantly by the countries highlighted above.

Western Pacific Region

To date, the Western Pacific Region is the least affected region on the globe, reporting the lowest number of COVID-19 cases and deaths. The cumulative number of cases in this region stands at approximately 313,000, with approximately 56,000 new cases reported in the previous fortnight (22% increase). This represents 1.6% of the global total number of new cases reported in the period. Cumulatively, the Western Pacific region accounts for 1.8% of all cases globally and 1.2% of all deaths. This region has so far reported a cumulative rate of 16.5 cases per 100,000 people and a mortality rate of 0.4 deaths per 100,000 population, which is low when compared to the global rates.

The highest numbers of cases in the region have been observed in the Philippines, China and Singapore. Their epidemic trajectories are shown in Figure 12. However, in the past fortnight the greatest numbers of new cases have been observed in the Philippines (54%) and Japan (21%). There were three countries/territories that did not report any new cases in the previous fortnight (Brunei Darussalam, New Caledonia and French Polynesia).

In the past fortnight Papua New Guinea has reported a large growth in case numbers, growing by 730% over the fortnight with a cumulative total of 110 cases. The new cases have predominantly been identified in Port Moresby, with the exception of two cases in Lae, and the national pandemic response controller indicates that community transmission is occurring. Port Moresby has been placed into a 14-day lockdown and community-based testing has commenced. An Australian Medical Assistance Team has been enacted to assist the COVID-19 response in the country. Vietnam has reported community transmission of a more infectious strain of the virus, with 144 new cases since 25 July, predominantly in the Da Nang area. Three deaths have also been reported, the country’s first. These occurred in older people with comorbidities.

South East Asia Region

In this fortnight, the South East Asia region has seen a large growth in new case numbers. Cumulatively the region has reported approximately 2.07 million cases and 44,900 deaths, with approximately 724,000 cases reported in the last fortnight (a 54% increase). Cumulatively, the region accounts for 11.9% of global cumulative cases and 6.7% of global cumulative deaths. Regionally, the per capita burden of disease is relatively low, compared to the global rates, at 103.8 cases and 2.2 deaths per 100,000 population, though the case rate has increased sharply in this reporting period.
The majority of the cases in the region have been observed almost exclusively in India, Bangladesh and Indonesia, which also comprise the greatest proportion of new cases in the previous fortnight, at 91%, 5% and 4% respectively. Their epidemic trajectories are shown in Figure 11. The remaining countries combined have reported only 3,418 cases. India reported the greatest rise in case count, increasing by 63% over the reporting period. The Maldives is the most affected country in the region per capita, reporting 701.1 cases per 100,000 people. Only Timor-Leste did not report a case in the previous fortnight.

Data considerations

Data were extracted from the NNDSS on 5 August 2020 for notifications received up to 2 August. Due to the dynamic nature of the NNDSS, numbers presented in this report are subject to revision and may vary from numbers previously reported and from case notifications released by states and territories.

Data were extracted from the FluCAN and SPRINT-SARI (Short Period Incidence Study of Severe Acute Respiratory Infection) databases on 8 August for data up to 7 August 2020.

FluCAN is a sentinel passive surveillance system which captures COVID-19 cases confirmed by nucleic acid testing admitted to participating hospitals. Case fatality is based on currently available data at the time of reporting and is likely to underestimate the true mortality.

SPRINT SARI is a hospital-based surveillance database that enables real time tracking and reporting of the sickest patients with COVID-19 in Australian hospitals and Intensive Care Units.

Definitions

‘Date of illness onset’ is derived from data collected by the NNDSS and represents the diagnosis date, or reported true onset of disease date. If unknown, the earliest of specimen collection date, notification date or notification receive date is used.

‘Notification received date’ is reported in the NNDSS and represents the date the case is first notified on the NNDSS. As notification can only occur after testing is completed and information processed, counts for a defined period will vary according to the date type used.

‘Cluster’ in relation to COVID-19 refers to two or more cases (who do not reside in the same household) that are epidemiologically related in
Figure 12: Number of COVID-19 cases (logarithmic scale) by selected country and days since passing 100 cases, up to 2 August 2020
time, place or person where a common source (such as an event or within a community) of infection is suspected but not yet established.

‘Outbreak’ in relation to COVID-19 refers to two or more cases (who do not reside in the same household) among a specific group of people and/or over a specific period of time where illness is associated with a common source (such as an event or within a community). Some states and territories may report a single case associated with a residential aged care facility as an outbreak.

Acknowledgements

This report represents surveillance data reported through CDNA as part of the nationally-coordinated response to COVID-19. We thank public health staff from incident emergency operations centres in state and territory health departments, and the Australian Government Department of Health, along with state and territory public health laboratories.

Appendix A: Background

Last updated 4 August 2020

Epidemiological parameters of SARS-CoV-2 infection and COVID-19 disease are under investigation and are likely to change as more information becomes available. The information provided in this Appendix comes from peer-reviewed and official sources. Pre-prints that have not been peer reviewed have been referenced and are identified in the text.

Modes of transmission

Human-to-human transmission of SARS-CoV-2 is primarily via droplets and fomites from an infected person to a close contact.25 Airborne transmission may occur through medical aerosol generating procedures, and although there are limited studies in the literature to evaluate the risk of specific procedures, it is prudent for health care workers to continue to undertake appropriate precautions.26 The potential for transmission by aerosols in other settings is the subject of discussion.27 SARS-CoV-2 may cause intestinal infection and viral shedding in faeces has been reported, but there are no reports of faecal-oral transmission.28 There is limited information about the potential for vertical transmission; however, SARS-CoV-2 RNA has been detected in placental tissue and amniotic fluid associated with a stillbirth in Belgium,29 suggesting it may be possible under some circumstances.

Several studies suggest that children do not play a key role in transmission and are unlikely to be the primary source of infections.30 Studies from the EU have suggested that child-to-adult transmission is uncommon.31,32

Incubation period

A systematic review of published and preprint studies has estimated the median incubation period of COVID-19 as between 5 and 6 days (ranging from 1 to 14 days).33,34

Infectious period

The infectious period is not well described due to a lack of studies using virus isolation to assess the presence of viable SARS-CoV-2 over time following infection.35 Viral RNA has been identified in respiratory tract specimens 1–2 days prior to symptom onset, and has been observed after symptom cessation.36 A retrospective analysis of 77 pairs of primary and secondary cases suggested that infectiousness may commence from 2.3 days before symptom onset, peaking at 0.7 days before symptom onset. It also suggested 44% of secondary cases may have been infected before the primary case was symptomatic.37 Cases can be infectious while not displaying symptoms, although it is not clear whether these individuals are pre-symptomatic or truly asymptomatic. Current World Health Organization (WHO) advice is that asymptomatic individuals are less infectious than people who display symptoms.38 However, a cross-sectional study in Massachusetts USA of residents and staff in aged care settings demonstrated that viral shedding was similar between people who were symptomatic and not symptomatic at the time of sampling.39 This study has not yet been peer reviewed.

Viral RNA levels peak in the first week of illness, suggesting transmission is most likely to occur early with infectivity gradually decreasing over time.36 In a Taiwanese study examining over 2,500 close contacts of 100 patients with COVID-19, all 22 secondary cases had their first exposure to the index case within six days of symptom onset. No infections were documented in the 850 contacts whose exposure was after six days.40
Immunology

No correlates of immunity have been established but two challenge trials of rhesus macaques suggest that individuals with neutralising antibody titres between 8 and 200 were protected from clinical signs of disease (but not viral shedding) when exposed to SARS-CoV-2 at 28 and 35 days after initial challenge.\textsuperscript{41,42} Cell-mediated immunity has also been demonstrated in recovered people, but the importance of cell-mediated and humoral immunity in clinical recovery and protection against infection and disease requires further study.

In a study of nine cases in Germany, around 50% of the patients seroconverted occurred seven days after symptom onset, and all patients had seroconverted by 14 days. Infectious virus was not able to be isolated from naso/oropharyngeal and sputum samples after the first 8 days of illness.\textsuperscript{36}

The duration of humoral antibody response is not well characterised. A cohort study of 96 SARS-CoV-2 infected people in the United Kingdom demonstrated that serum neutralising antibody responses waned after 40 days post infection, and individuals who had experienced milder symptoms had no neutralisation response at around 60 days post infection.\textsuperscript{43} This study has not been peer reviewed.

The potential for reinfection or recrudescence of infection is also unclear. However, analysis from the Korea Centres for Disease Control and Prevention, of 108 cases who tested positive after previously being cleared from isolation, found live virus was unable to be cultured from any cases selected for testing.\textsuperscript{44}

Viral genomics

Since December 2019, the virus has diversified into multiple lineages as it has spread globally, with some degree of geographical clustering. There are currently 2,728 SARS-CoV-2 genome sequences available from Australian cases on the global sequence repository, GISAID. These sequences are dispersed throughout the global lineages, reflecting multiple concurrent introductions into Australia.\textsuperscript{45–47} Recent Australian SARS-CoV-2 sequences from the last month include 31 collected from NSW and 7 from South Australia. Most of these sequences belong to the B.1.1.25 lineage, reflecting ongoing local transmission of this lineage. Genomic epidemiology continues to be used to support epidemiological investigations, particularly for confirming presumed transmission pathways. It has proven particularly useful for linking those cases classified as ‘locally-acquired – contact not identified’ to known genomic clusters, highlighting the utility of virus sequencing to informing the public health response.\textsuperscript{45,46}

Clinical features

COVID-19 presents as mild illness in the majority of cases, with cough and fever the most commonly reported symptoms (see Appendix B). Severe or fatal outcomes are more likely to occur in the elderly or those with comorbid conditions.\textsuperscript{25,48}

Some COVID-19 patients show neurological signs such as headache, nausea and vomiting. There is evidence that SARS-CoV-2 viruses are not always confined to the respiratory tract and may invade the central nervous system causing neurological signs and symptoms. As such, it is possible that invasion of the central nervous system is partially responsible for the acute respiratory failure of COVID-19 patients.\textsuperscript{49}

Impairment or loss of the sense of smell (hyposmia/anosmia) or taste (hypoguesia/ageusia) is commonly associated with COVID-19.\textsuperscript{50–52} This is supported by research finding a biological mechanism for the SARS-CoV-2 virus to cause olfactory dysfunction.\textsuperscript{53,54} Case reports have also linked SARS-CoV-2 infection with less common neurological syndromes including encephalopathy, encephalitis, Guillain-Barré syndrome and acute cerebrovascular disease.\textsuperscript{52}

Several studies have also identified linked cardiovascular diseases to COVID-19.\textsuperscript{55–57} Vascular
inflammation has been observed in a number of cases and may be a potential mechanism for myocardial injury which can result in cardiac dysfunction and arrhythmias.

COVID-19 disease in children is more likely to be mild and self-limiting, compared to adults. Internationally, children make up a small proportion of confirmed COVID-19 cases, with those shown to be infected either presenting with milder symptoms than adults or remaining asymptomatic. However, the greater likelihood of mild clinical presentation in children may result in lower testing and case detection in this cohort. Studies have also shown that hospital admission is inversely related to age. From European reporting, death associated with COVID-19 has been rare among those aged less than 15 years, with 4 deaths reported from 44,695 cases, as at 13 May 2020.30

There have been reports of a rare clinical presentation of paediatric inflammatory multisystem syndrome resembling Kawasaki disease temporally associated with SARS-CoV-2 infection in children. However, evidence of the association between COVID-19 and the development of a Kawasaki-like disease is currently inconclusive and further investigation is needed due to variability in clinical presentations in reported paediatric cases.58,59

Treatment

Current clinical management of COVID-19 cases focuses on early recognition, isolation, appropriate infection control measures and provision of supportive care.60 Whilst there is no specific antiviral treatment currently recommended for patients with suspected or confirmed SARS-CoV-2 infection, multiple clinical trials are underway to evaluate a number of therapeutic agents, including remdesivir, lopinavir/ritonavir, and chloroquine or hydroxychloroquine.61,62

An open-label randomised controlled trial did not find a significant impact of hydroxychloroquine treatment on disease progression for hospitalised patients with mild to moderate COVID-19, with those receiving treatment also reporting a higher number of adverse events.63 Similarly, an open-label randomised controlled trial of lopinavir/ritonavir among hospitalised patients found no benefit for time to clinical improvement.64 WHO announced the interruption of clinical trials of hydroxychloroquine and lopinavir/ritonavir under the ‘Solidarity Trial’ on 4 July 2020.65

Results for remdesivir treatment have been mixed, with one randomised double-blind placebo-controlled trial finding patients recovered 31% faster and a lower mortality rate (8.0% compared with 11.6% among placebo patients),66 while another found no effect.67 The Therapeutic Goods Administration has granted provisional approval for use of remdesivir in hospitalised adults and adolescents with severe COVID-19 symptoms.68

As at 27 July 2020, the WHO reports that at least 25 candidate vaccines are in clinical trials and 139 are in preclinical evaluation.69

Research from the UK has found dexamethasone could significantly reduce death in critically ill patients.70 Yet to be published, the preliminary findings announcing by Oxford University reported a 30% reduction in deaths for patients with severe respiratory symptoms. Reduced mortality was observed in ventilated cases and cases requiring oxygen support. No benefit was observed for mild to moderate cases. There are no barriers to the use of dexamethasone in Australian patients who are critically ill, such as cases who require ventilation or oxygen support.70

Figure B.1: Variation in combinations of COVID-19 symptoms in confirmed cases as at 2 August 2020, Australia

This figure shows the variation in combinations of symptoms observed in reported cases (n = 12,636) for the five most frequently observed symptoms (cough, fever, headache, sore throat, runny nose). The horizontal bars on the left show the frequency of symptom occurrence in any combination with other symptoms. The circles and lines indicate particular combinations of symptoms observed in individual patients. The vertical green bars indicate the frequency of occurrence of the corresponding combination of symptoms.
Appendix C: Frequently asked questions

Q: Can I request access to the COVID-19 data behind your CDI fortnightly reports?

A: National notification data on COVID-19 confirmed cases is collated in the National Notifiable Disease Surveillance System (NNDSS) based on notifications made to state and territory health authorities under the provisions of their relevant public health legislation.

Normally, requests for the release of data from the NNDSS requires agreement from states and territories via the Communicable Diseases Network Australia, and, depending on the sensitivity of the data sought and proposed, ethics approval may also be required.

Due to the COVID-19 response, unfortunately, specific requests for NNDSS data have been put on hold. We are currently looking into options to be able to respond to data requests in the near future.

We will continue to publish regular summaries and analyses of the NNDSS dataset and recommend the following resources be referred to in the meantime:

- State and territory public health websites.

Q: Why have the reports changed from weekly to fortnightly?

A: The change to fortnightly reporting is to allow more time for an in-depth analysis of the NNDSS data, therefore enhancing the contents of the report.

Q: Can I request access to data at post-code level of confirmed cases?

A: Data at this level cannot be released without ethics approval and permission would need to be sought from all states and territories via the Communicable Diseases Network Australia. As noted above, specific requests for NNDSS data are currently on hold.

Where current or recent reported case numbers are high enough to justify it, a GIS/mapping analysis of cases will be included in the Communicable Diseases Intelligence COVID-19 epidemiology report. In order to protect privacy of confirmed cases, data in this map will be presented at SA3 level.

Q: Where can I find more detailed data on COVID-19 cases?

A: We are currently looking into ways to provide more in-depth epidemiological analyses of COVID-19 cases, with regard to transmission and severity, including hospitalisation. These analyses will continue to be built upon in future iterations of the Communicable Diseases Intelligence report.
